DATABASE SYSTEMS

Sorting & Aggregations

Homework #3 is due Sunday Oct 5th @ 11:59pm

Mid-Term Exam is on Wednesday Oct 8th
→ Lectures #01–11 (inclusive)
→ Study guide is now available (@126)
→ Bring your CMU ID!

Project #2 is due Sunday Oct 26th @ 11:59pm

We are now going to talk about how to execute queries using the DBMS components we have discussed so far.

Next four lectures:
→ Operator Algorithms
→ Query Processing Models
→ Runtime Architectures

| *Query Planning* |
| --- |
| *Operator Execution* |
| *Access Methods* |
| *Buffer Pool Manager* |
| *Disk Manager* |

The operators are arranged in a tree.

Data flows from the leaves of the tree up towards the root.
→ We will discuss the granularity of the data movement next week.

The output of the root node is the result of the query.

```
SELECT R.id, S.cdate
  FROM R JOIN S
    ON R.id = S.id
 WHERE S.value > 100
```

π R.id, S.cdate

⋈ R.id=S.id

σ value>100
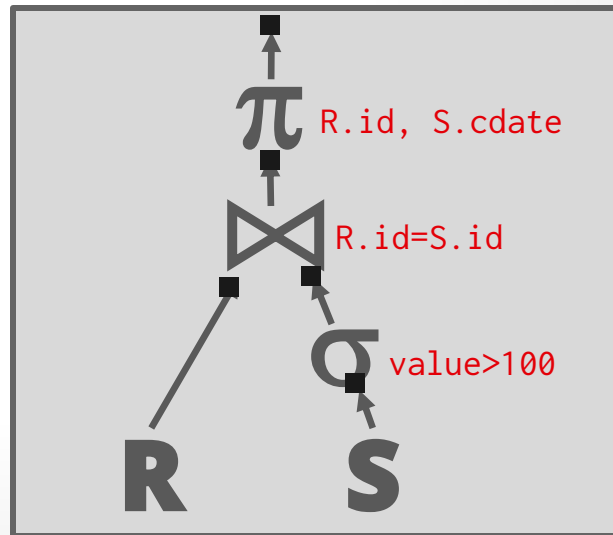

R   S

Just like it cannot assume that a table fits entirely in memory, a disk-oriented DBMS cannot assume that query results fit in memory.

We will use the buffer pool to implement algorithms that need to spill to disk.

We are also going to prefer algorithms that maximize the amount of sequential I/O.

WHY DO WE NEED TO SORT?

Relational model/SQL is <u>unsorted</u>.

Queries may request that tuples are sorted in a specific way (**ORDER BY**).

But even if a query does not specify an order, we may still want to sort to do other things:
→ Trivial to support duplicate elimination (**DISTINCT**).
→ Bulk loading sorted tuples into a B+Tree index is faster.
→ Aggregations (**GROUP BY**).

If data fits in memory, then the DBMS can use a standard sorting algorithm.
→ Optimized algorithms if data is mostly sorted (VergeSort).
→ Otherwise use your favorite (QuickSort, TimSort, RadixSort).
→ Many online visualization tools.

If data does not fit in memory, then we need to use a technique that is aware of the cost of reading and writing disk pages …

For a given input **run** (i.e., list of key/value pairs), sort it based on a comparison function and sorting parameters.

Key: The attribute(s) to compare to compute the sort order.

Value: Two choices
→ Tuple (**early materialization**).
→ Record ID (**late materialization**).

EXTERNAL MERGE SORT

Divide-and-conquer algorithm that splits data into separate **runs**, sorts them individually, and then combines them into longer sorted runs.

Phase #1 – Sorting
→ Sort chunks of data that fit in memory and then write back the sorted chunks to a file on disk.
→ Pick your favorite in-memory sorting algorithm.

Phase #2 – Merging
→ Combine sorted runs into larger chunks.

2-WAY EXTERNAL MERGE SORT

We will start with a simple example of a 2-way external merge sort.
→ "2" is the number of runs to merge into a new run for each pass.

Data is broken up into N pages.

The DBMS has a finite number of B buffer pool pages to hold input and output data.

SIMPLIFIED 2-WAY EXTERNAL MERGE SORT

Pass #0

→ Read one page of the table into memory
→ Sort page into a "run" and write it back to disk
→ Repeat until the whole table has been sorted into runs

Pass #1,2,3,…

→ Recursively merge pairs of runs into runs twice as long
→ Need at least 3 buffer pages (2 for input, 1 for output)
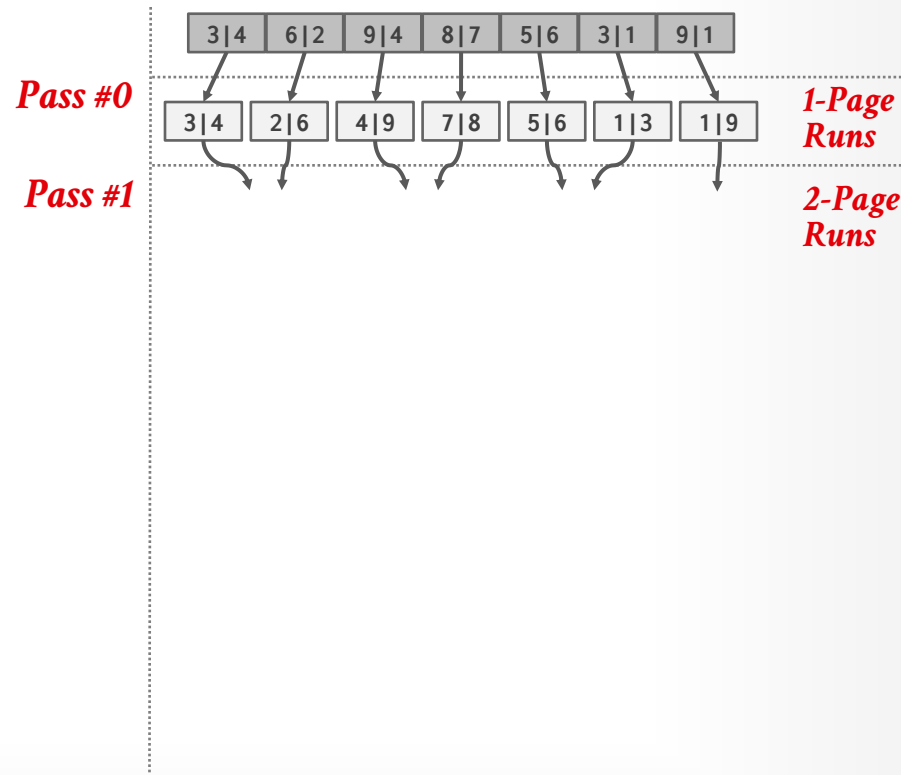

SIMPLIFIED 2-WAY EXTERNAL MERGE SORT

In each pass, the DBMS reads and writes every page in the file.

Number of passes
$$= 1 + \lceil \log_2 N \rceil$$

Total I/O cost
$$= 2N \cdot (\# \text{ of passes})$$

3|4	6|2	9|4	8|7	5|6	3|1	9|1

Number of passes
$$= 1 + \lceil \log_2 N \rceil$$

Total I/O cost
$$= 2N \cdot (\text{# of passes})$$

Pass #0 — 1-Page Runs

Pass #1 — 2-Page Runs

Pass #2 — 4-Page Runs

Pass #3 — 8-Page Runs

SIMPLIFIED 2-WAY EXTERNAL MERGE SORT

This algorithm only requires three buffer pool pages to perform the sorting ($B=3$).
→ Two input pages, one output page

But even if we have more buffer space available ($B>3$), it does not effectively utilize them if the worker must block on disk I/O…

GENERAL EXTERNAL MERGE SORT

Pass #0
$\rightarrow$ Use **B** buffer pages
$\rightarrow$ Produce $\lceil N / B \rceil$ sorted runs of size **B**

Pass #1,2,3,…
$\rightarrow$ Merge **B-1** runs (i.e., M-way merge)

Number of passes = $1 + \lceil \log_{B\text{-}1} \lceil N / B \rceil \rceil$

Total I/O Cost = $2N \cdot (\text{\# of passes})$

EXAMPLE

Determine how many passes it takes to sort 108 pages with 5 buffer pool pages: **N=108**, **B=5**

→ **Pass #0:** $\lceil N / B \rceil$ = $\lceil 108 / 5 \rceil$ = 22 sorted runs of 5 pages each (last run is only 3 pages).

→ **Pass #1:** $\lceil N' / B\text{-}1 \rceil$ = $\lceil 22 / 4 \rceil$ = 6 sorted runs of 20 pages each (last run is only 8 pages).

→ **Pass #2:** $\lceil N'' / B\text{-}1 \rceil$ = $\lceil 6 / 4 \rceil$ = 2 sorted runs, first one has 80 pages and second one has 28 pages.

→ **Pass #3:** Sorted file of 108 pages.

$$1 + \lceil \log_{B\text{-}1} \lceil N / B \rceil \rceil = 1 + \lceil \log_4 22 \rceil = 1 + \lceil 2.229... \rceil$$
$$= \textbf{4 passes}$$

DOUBLE BUFFERING

Prefetch next run in the background and store in a second buffer while processing the current run.
→ Overlap CPU and I/O operations
→ Reduces effective buffers available by half

COMPARISON OPTIMIZATIONS

Approach #1: Code Specialization
→ Instead of providing a comparison function as a pointer to sorting algorithm, create a hardcoded version of sort that is specific to a key type.

Approach #2: Suffix Truncation
→ First compare a binary prefix of long **VARCHAR** keys instead of slower string comparison. Fallback to slower version if prefixes are equal.

Approach #3: Key Normalization
→ Transform variable-length attribute(s) into a single encoded/padded string that preserves sort order.

USING B+TREES FOR SORTING

If the table that must be sorted already has a B+Tree index on the sort attribute(s), then we can use that to accelerate sorting.
→ Some DBMSs support prefix key scans for sorting.

Retrieve tuples in desired sort order by simply traversing the leaf pages of the tree.

Cases to consider:
→ Clustered B+Tree
→ Unclustered B+Tree

CASE 1: CLUSTERED B+TREE

Traverse to the left-most leaf page, and then retrieve tuples from all leaf pages.

This is always better than external sorting because there is no computational cost, and all disk access is sequential.

B+Tree Index

101   102   103   104

Tuple Pages
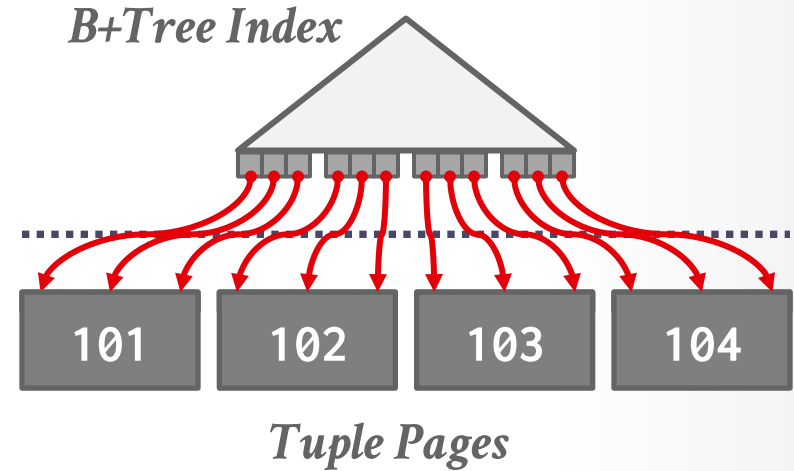

CASE #2: UNCLUSTERED B+TREE

Chase each pointer to the page that contains the data.

This is almost always a bad idea except for Top-N queries where N is small enough relative to total number of tuples in table.
→ In general, one I/O per data record.

B+Tree Index

| 101 | 102 | 103 | 104 |
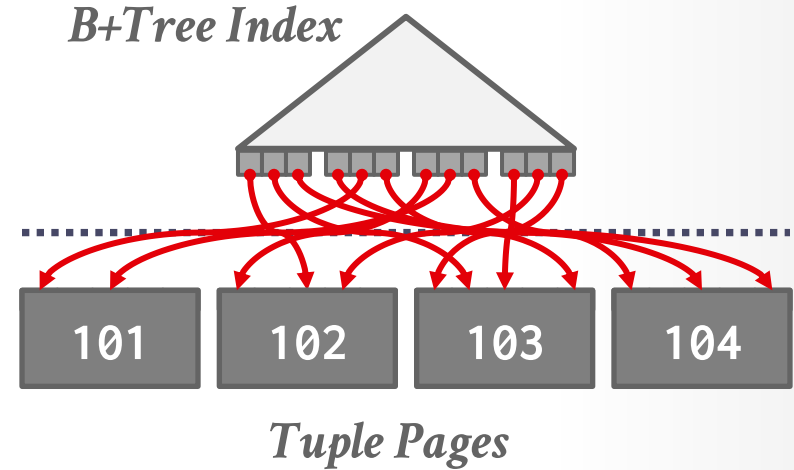

Tuple Pages

Collapse values for a single attribute from multiple tuples into a single scalar value.

The DBMS needs a way to quickly find tuples with the same distinguishing attributes for grouping.

Two implementation choices:
→ Sorting
→ Hashing

ALTERNATIVES TO SORTING

What if we do <u>not</u> need the data to be ordered?
→ Forming groups in **GROUP BY** (no ordering)
→ Removing duplicates in **DISTINCT** (no ordering)

Hashing is a better alternative in this scenario.
→ Only need to remove duplicates, no need for ordering.
→ Can be computationally cheaper than sorting.

HASHING AGGREGATE

Populate an ephemeral hash table as the DBMS scans the table. For each record, check whether there is already an entry in the hash table:
→ **DISTINCT**: Discard duplicate
→ **GROUP BY**: Perform aggregate computation

If everything fits in memory, then this is easy.

If the DBMS must spill data to disk, then we need to be smarter…

Divide-and-conquer approach to computing an aggregation when data does not fit in memory.

Phase #1 – Partition
→ Split tuples into buckets based on hash key
→ Write them out to disk when they get full

Phase #2 – ReHash
→ Build in-memory hash table for each partition and compute the aggregation

PHASE #1: PARTITION

Use a hash function h_1 to split tuples into **partitions** on disk.
→ A partition is one or more pages that contain the set of keys with the same hash value.
→ Partitions are "spilled" to disk via output buffers.

Assume that we have **B** buffers.

We will use **B-1** buffers for the partitions and **1** buffer for the input data.

PHASE #1: PARTITION

```
SELECT DISTINCT cid
  FROM enrolled
 WHERE grade IN ('B','C')
```

enrolled (sid, cid, grade)

sid	cid	grade
53666	15-445	C

B-1

For each partition on disk:
→ Read it into memory and build an in-memory hash table based on a second hash function h_2.
→ Then go through each bucket of this hash table to bring together matching tuples.

This assumes that each partition fits in memory.

```
SELECT DISTINCT cid

During the rehash phase, store pairs of the form
(**GroupKey**➔**RunningVal**)

When we want to insert a new tuple into the hash table
as we compute the aggregate:
→ If we find a matching **GroupKey**, just update the **RunningVal**
  appropriately
→ Else insert a new **GroupKey**➔**RunningVal**

HASHING SUMMARIZATION

```
SELECT cid, AVG(s.gpa)
  FROM student AS s, enrolled AS e
 WHERE s.sid = e.sid
 GROUP BY cid
```

Running Totals

AVG(col)   ➜ (**COUNT**, **SUM**)
MIN(col)   ➜ (**MIN**)
MAX(col)   ➜ (**MAX**)
SUM(col)   ➜ (**SUM**)
COUNT(col) ➜ (**COUNT**)

CONCLUSION

Choice of sorting vs. hashing is subtle and depends on optimizations done in each case.

We already discussed the optimizations for sorting:
→ Chunk I/O into large blocks to amortize costs
→ Double-buffering to overlap CPU and I/O

Nested Loop Join

Sort-Merge Join

Hash Join
